Editor’s Note: Oracle database technology expert Scott Jesse has seen a lot of changes over the course of his Oracle career. Today’s Oracle customers want to learn more about Oracle’s strategic capabilities that can be leveraged on any platform and especially MS Windows. In his debut article, and the first of many, Scott provides a very detailed explanation for implementing Oracle 10g on Windows including things to know, best practices for maximizing memory usage, and overviews of using AWE and RAC technology.

Introduction

Word on the street these days is that Linux is hot. In fact, I recently came across an Oracle CD that had this on the jacket: “Linux - Very Hot. Oracle On Linux: Very Cool!” It is hard to argue with this when looking at the database market share numbers for 2004. Gartner Dataquest’s 2004 RDBMS market share report shows that the Linux RDBMS market grew 118%, with Oracle holding 80% of that market. But, lost in the shuffle of that staggering triple-digit growth and 80% market share number is the fact that the RDBMS market on Windows also grew at a rate of 10%, while Oracle on Windows grew by 8.5%. These numbers may seem small when viewed as a percentage, but consider that the overall RDBMS market revenue for Windows in 2004 totaled just over $3 billion, whereas Linux market revenue was $650 million in comparison. So – if you are one of those running Oracle on Windows, you are not alone.

As a support engineer with Oracle for the past nine years, I have worked with hundreds (probably thousands) of customers running the Oracle RDBMS on Windows. During those years I have learned the ins and outs of Oracle on Windows, and the ups and downs of working on the Windows platform. The problems and challenges of those implementations have been issues across the board, ranging from basic how-to’s for a new “DBA”, to assisting in designing and maintaining highly-available mission-critical databases capable of running an entire company’s business. While there are many varied challenges in any implementation, the most common by far that I have encountered with Oracle on the Windows platform is the challenge of juggling memory to get the most out of the Oracle RDBMS. Therefore, the focus of this article is to give the DBA, whether novice or veteran, tips and insights into how to get the most out of Oracle and Windows, and make your database implementation as successful as possible.

Understanding the Oracle Architecture on Windows

To begin with, let’s go over the architecture of Oracle on the Windows platform. This is a main component in what makes Windows unique and challenging, as compared to other operating systems. On UNIX and Linux operating systems, the Oracle database is implemented as multiple processes, using shared memory management functionality to facilitate communications between the processes. Thus, the Oracle RDBMS itself is made up of a set of distinct, separate processes, including background processes and foreground processes. Well-known examples of background processes are PMON, SMON, LGWR, DBWR, etc.

On Windows, Oracle is implemented as a single process, running as an executable called oracle.exe. Within this single process, the functionality of PMON, SMON, LGWR, DBWR, etc., is still the same as on any other platform, however, the difference is that these background “processes” are actually implemented as threads of a single process – that process being the aforementioned “oracle.exe”. So, while PMON still exists, you will not see a separate PMON process running on a Windows machine, as this process is actually just a thread of the oracle executable.

By the same token, user connections, seen as foreground processes on UNIX/Linux environments, become threads within the same oracle executable – again, all running under a single process on Windows. So, the end result is one process comprised of threads that are considered to be both background “threads”...
(PMON, SMON, etc.) and foreground “threads” (user application connections) for the database. Therefore, if you are attempting to view processes through the normal means on Windows (i.e., via Task Manager), you will not see anything BUT the Oracle process. In a future article, I will discuss how to identify the threads within the Oracle process, but for now, the key is in understanding how Oracle is architected.

**Why Threads?**

So, why this deviation on the Windows platform, when UNIX platforms operate as separate processes? In fact, in the earliest releases of Oracle on Windows, Oracle attempted to stick with the convention of having separate processes – but the shared memory implementation between processes on Windows was deemed to be too slow and inefficient for Oracle’s needs. The simple fact is that Windows as an operating system lends itself to an architecture where applications run most efficiently as a single process with multiple threads. Oracle quickly modified the architecture to conform to this principle and has stuck with that model since the early days of Oracle 7. The result is a high-performing, feature-rich RDBMS, which has the same core components and the same look and feel across all major server platforms, but with modifications under the covers to make it perform at its highest efficiency on the Windows platform.

The next logical question is, “Why does this really matter?” As I have just noted, Oracle has the same look and feel and rock solid reliability on every platform – so why bother yourself with the internals and with questions about thread-based versus process-based architectures? Obviously there are many reasons, but the most crucial, which just so happens to be the topic of this article, is memory.

To digress momentarily, I would like to discuss certain realities that I see today from my perspective working within Oracle Support. It is a fact of the marketplace that the vast majority of Windows servers being used in the workplace today are still 32-Bit machines. Windows is not alone in this category, as the majority of Linux servers in use today are also 32-Bit machines. Anecdotally, I would estimate that of the customers I deal with on a daily basis who are on Windows or Linux, around 75% to 80% are still on 32-Bit versions of the OS – though that is changing more quickly of late.

Because of this fact, Windows and Linux are unique, so Oracle has released both 32-Bit and 64-Bit 10g versions for Windows and Linux operating systems. This is not true on any other platform, as Oracle did not release a version of Oracle 10g for any other 32-Bit OS’s – i.e., for Sun Sparc Solaris, AIX, HP-UX PA-RISC, etc. Oracle has released only a 64-Bit version of Oracle Database 10g, but my expectation is that Oracle will continue to release new versions of the RDBMS for 32-Bit Windows and Linux for the foreseeable future.

In a 32-Bit world, there are certain limitations that get magnified with a single-process architecture, the foremost of which is addressable memory. Any 32-bit process, no matter the operating system, can only address up to 4 GB of memory (to confirm this, write out 32-bits in binary as all 1s, and then convert from binary to decimal):

<table>
<thead>
<tr>
<th>Binary:</th>
<th>Decimal:</th>
</tr>
</thead>
<tbody>
<tr>
<td>11111111 11111111 11111111 11111111</td>
<td>4294967295</td>
</tr>
</tbody>
</table>

Operating systems differ in how much of that 4 GB of addressable memory they will allow a user application to take advantage of. On Windows, by default, a single process is only allowed to directly address half of that 4 GB, as the other half is reserved for operating system kernel memory.

What this means is that if running with the default settings on a Windows server, the oracle.exe process, which we previously discussed, can only directly address a total of 2 GB of memory. This in turn means that all memory for the database, including the SGA and all PGA memory for individual sessions, is counted towards this total. Add to this the overhead associated with the Oracle process itself (which is about 100 MB), and 1 MB of stack space reserved for every thread within the process address space, and you can see that 2 GB of memory can be very quickly consumed.

**Monitoring Oracle Memory Usage**

The first step in managing memory usage is knowing how to accurately gauge its usage. When the Oracle process reaches the maximum addressable memory limit, there are a couple of different errors that may occur, depending on the situation.
If an existing connection/session is attempting to allocate more memory, for example, if an existing session attempts to do a sort in memory, or open a new cursor, and the oracle.exe process cannot address any more memory, an ORA-4030 error will occur.

The ORA-4030 error text is fairly straightforward:

“out of process memory when trying to allocate %s bytes”

Thus there is not a lot of mystery in this error.

However, if a new connection attempt is being made, the client will normally first make contact with the listener, where the thread is initially spawned, and the listener then attempts to hand that thread off to the oracle executable. The initial contact with the listener is successful, but an error occurs in the handoff, because the oracle.exe does not have enough remaining address space to spawn the thread. The resulting error here is an ORA-12500.

The ORA-12500 error text is fairly straightforward:

“TNS:listener failed to start a dedicated server process”

This is a slightly more cryptic error, and, on Windows, it is technically an inaccurate description, because we are actually trying to start a thread, not a process. Unfortunately, this error often leads a DBA down the wrong path, attempting to troubleshoot a networking problem, when in fact the problem is that the database process has exhausted all available memory. Therefore, it is critical to not only know what the memory limitations are, but how to accurately measure the memory usage, in order to quickly identify the source of a problem (or preferably, to head off a problem). It is surprising to me how many Systems Administrators and DBAs use Windows Task Manager as the only tool for monitoring memory utilization for a given process. In many cases, they may even be aware of the aforementioned limitations, but are certain that they do not have a problem because Task Manager only shows that the Oracle process is using 1.5 GB (as an example).

What Task Manager is not showing you is the total memory addressed by the process. By default, Task Manager has only a Mem Usage column, which is simply the working set, or recently used/touched memory pages for the process. You can add a second memory column in Task Manager called VM Size, but that still does not show the total picture, as it only show memory committed by the process. In addition to committed memory, it is possible to have memory reserved, but not committed. This memory still counts against the addressable memory limit, but will not be shown anywhere in Task manager. Instead, you must run the Windows Performance Utility.

You can access Perfmon using the navigation path:

1. Highlight System Monitor on the left-hand side
2. To monitor memory, first click on the “+” icon along the top menu bar. This will open the dialog box to add counters to the chart.

As you can see in Figure 1, you can monitor a remote computer or a local computer.

3. Under Performance Object, select “Process” and, from the list of counters, choose “Virtual Bytes”.
4. On the right-hand side, select “oracle” from the list of (process) instances, and choose “Add” to begin charting the Virtual Bytes for the process.

This value for “Virtual Bytes” gives you the true, accurate count of all memory being addressed by the oracle.exe process.

Where Is That Memory Going?
So what is using this memory within the Oracle process? You can use the following as a rough calcu-
lation for the total memory used by the process, which should be roughly equivalent to the value for Virtual Bytes:

\[
\text{Process Overhead (approximately 100 MB) + Thread Stack (1 MB x \# of threads)} + \\
\text{Total SGA + Total PGA} = \text{Virtual Bytes for oracle.exe}
\]

The total SGA is easily calculated by looking at init.ora parameters and/or querying v$sga – but calculating/limiting the total PGA used is a bit more involved. You can limit the amount of PGA memory used for operations (such as sorts and hash joins) by setting the PGA_AGGREGATE_TARGET parameter, but this will not place a limit on memory used for cursors. The total number of cursors can be limited by setting the OPEN_CURSORS parameter, but still, this will not limit the size of any single cursor. An application or a user can open a single large cursor, which might consume a large amount of memory (say a PL/SQL table or varray in memory), so there will always be a variable component to PGA memory that cannot be fully controlled. To calculate current PGA memory used, you can run a query against the v$sysstat and v$sesstat views, such as the queries shown here:

- Of particular interest are the values for UGA memory and PGA memory. The v$sysstat view gives you a sum of all PGA/UGA memory used by all sessions. To drill down further to determine what individual sessions are actually using the most memory, you can use the v$sesstat view, using the values for statistic# as indicated in the above query results.

For example:

```sql
SQL> select * from v$sesstat where statistic# in (20,21,25,26) order by value;
```

Once you know the SID, you can join with v$session to get more information on that particular session and what it may be doing. If a session or set of sessions is using an inordinate amount of PGA, the application code being executed should be investigated further to look for poor management of cursors as a possible source of PGA memory growth.

### Stack Space for Threads

I also noted above that each thread within the oracle.exe uses 1 MB of stack space. To view the current stack size of a given executable, you can run the orastack utility, which comes with Oracle10g (and earlier versions), and pass the executable name.

For example:

```
D:\oracle\Ora10g\BIN>orastack tnslsnr.exe
Dump of file tnslsnr.exe
Current Reserved Memory per Thread = 1048576
Current Committed Memory per Thread = 4096
```

Orastack’s main purpose is to be able to change the stack size. To see how to do this, just run “orastack” by itself. Note that the process must be stopped in order for the stack size of an executable to be changed. I would also recommend that you change the stack both for the tnslsnr.exe and for the oracle.exe, as the majority of threads are actually created first by the listener, but many threads can also be spawned directly from the oracle.exe (background processes, shared servers, job_queue processes, etc.). A value of 500k can be used with no real downside. Here is an example of changing the tnslnr.exe:

```
D:\>net stop OracleOraDb10g_home1TNSListener
The OracleOraDb10g_home1TNSListener service is stopping.
```

```
D:\>net start OracleOraDb10g_home1TNSListener
The OracleOraDb10g_home1TNSListener service was started successfully.
```

```
D:\orastack D:\oracle\Ora10g\BIN\tnslsnr.exe 500000
Dump of file D:\oracle\Ora10g\BIN\tnslsnr.exe
```

<table>
<thead>
<tr>
<th>STATISTIC#</th>
<th>NAME</th>
<th>VALUE</th>
</tr>
</thead>
<tbody>
<tr>
<td>20</td>
<td>session uga memory</td>
<td>3205664</td>

<td>4400</td>
</tr>
</tbody>
</table>
Current Reserved Memory per Thread = 1048576
Current Committed Memory per Thread = 4096

New Reserved Memory per Thread = 500000

Of course, another way to reduce the total stack size for threads within the oracle.exe is to reduce the total number of threads. In this vein, using shared servers on Windows is another strategy that must be given careful consideration. I have worked with many customers running Oracle on Windows who have successfully used shared server implementations to manage over 1000 concurrent connections to the database, while keeping the total thread count at or below 100 threads.

**Increasing Memory Available to Oracle**

So far we discussed the known limitations and Windows’ default memory settings out of the box. We also touched on how to monitor the available memory and determine where it is being used, as well as on how to minimize your memory utilization. But be honest – what everyone really wants to know is – how do I get to use MORE memory? This is what really matters. So, we will now delve into strategies for getting more memory out of the system, including:

- Increasing the addressable memory from the default of 2 GB
- Taking advantage of PAE / AWE / VLM
- Implementing RAC for scalability
- Moving to 64-Bit.

**Increasing Directly Addressable Process Memory on Windows**

As noted previously, the addressable memory for a 32-Bit process is limited to 4 GB, but Microsoft Windows reserves half of that for kernel memory, leaving only half (the other 2 GB) for the process (oracle.exe). Depending on the version of Windows that you are running (i.e., if you are on Advanced Server or Enterprise Server versions of Windows), you can change that dynamic by adding a switch to the boot.ini file. Microsoft refers to this as 4GT RAM tuning, though the switch itself is actually a /3GB switch. The boot.ini file is a hidden file found at the root of the boot drive, whichever drive that is (usually C:). Adding the /3GB switch to the correct boot line will produce a boot.ini which looks something like this:

```
scsi(0)disk(0)rdisk(0)partition(1)
WINNT= 
"Microsoft	Windows	2000	Advanced	Server"	/fastdetect	/3GB
```

After setting the /3GB switch in the boot.ini, the server must be rebooted for that change to take effect. Once this is done, the oracle executable will be able to directly address 3 GB, with no other changes necessary. The additional memory can be used by any component that you desire; it can be used for increasing any component of the SGA, or by allowing additional PGA utilization, or additional threads, etc. There are no restrictions on how this memory is used - you effectively increase your addressable memory by 50%. On the surface, this seems like a no-brainer, but as with most things in life, there is a tradeoff. By setting the /3GB switch, the memory available for the operating system kernel memory is effectively cut in half. So what is the impact of this?

**Kernel Memory Impact with /3GB Enabled**

Operating system kernel memory on Windows is essentially divided into three major areas - the Paged Pool, the Non-Paged Pool, and memory set aside for Free System Page table entries (PTEs). With the default settings (no /3GB switch) the Paged Pool can max out at around 360 MB, the Non-Paged Pool can max out at around 256 MB, and Free System Page table entries are abundant. However, when setting the /3GB switch, the Paged Pool maximum becomes 256 MB, Non-Paged Pool maximum becomes 128 MB, and Free System Page table entries become scarce.

So while I strongly recommend using the /3GB switch wherever possible, it is also highly advisable to monitor these kernel memory counters to ensure that you are not exceeding these thresholds. Symptoms of exhausting kernel memory space include instability of the operating system and vague problems such as unexplained hangs, Disk I/O problems, or exceedingly poor performance. Specific problems include OS errors such as an OS error 1450 or OS 10055.

When monitoring these kernel memory values, pay particular attention to Non-Paged Pool and Free System Page table entries (PTEs). Non-Paged Pool is an increasing counter, meaning that as more resources are consumed, the higher this value will grow. As it approaches the maximum of 128 MB, you are more likely to experience instability of the operating system.

On the other hand, Free System PTEs is a decreasing counter, meaning that as more resources are used on the system, the number of Free PTEs decreases. Therefore, as this counter approaches 0, you are more likely to experience problems. Again, these values can and should be monitored using the Windows Performance Utility as shown in Figure 2.
Because the ability to increase the addressable memory by 50% is an opportunity that is too valuable to pass up, I almost always recommend this to customers who are constrained by memory, with the caveat that kernel memory be closely monitored. As such, throughout the rest of this article, I will be assuming a value of 3 GB is the maximum for addressable memory. If you choose not to enable this switch, simply substitute in a value of 2 GB whenever I reference 3 GB as the maximum value.

Should you find that Free System PTEs are running low, you may be able to do some fine-tuning. Adding in the /USERVA switch to the boot.ini may allow you to give a small portion of the 3 GB back to the OS, thus putting you over the top for kernel memory needs. See Metalink Note # 297498.1 and Microsoft Article #810371 for more details on this.

On the other hand, if you find that Non-Paged Pool is being eaten up, you may need to use utilities such as Poolmon, which comes with the Windows Resource Kit, to drill deeper into where the Non-Paged Pool consumption is originating. Depending on the source of the growth, you may find that updating some device drivers (which reside in the Non-Paged Pool) will put a stop to excessive memory growth.

**Accessing Additional Memory Indirectly Using AWE**

A question that I get asked by many customers indicates a common misconception on the 32-Bit Windows platform – that question usually goes along the lines of something like this – “My Windows 2003 Server has 16 GB of RAM. How can I use all of that memory?” This question is frequently asked in light of the revelation that in spite of having that much memory, a single process can only address a maximum of 3 GB of memory. So, what is one to do with all of that additional memory?

The answer to this is twofold: First, realize that the 32-Bit address space restriction is on a “per-process” basis. So, if you have multiple processes, each one can separately address up to 3 GB. You may have additional processes in the form of an additional Oracle instance (for example, an ASM instance), or you may have some other third-party application, running as its own process, which can take advantage of that additional memory as well. However, it is also possible to allow a single process, i.e., the oracle.exe for one instance, to indirectly access that memory. Aside from setting the /3GB switch in the boot.ini, it is also possible to set the /PAE switch.

PAE stands for Physical Address Extensions, which essentially is a term for the ability to address an additional 4 bits on the Intel Processor (giving you 36-Bits of address space). Those additional 4 bits must be accessed through a window that is carved out of the base 32-Bits – this is done on the Windows platform via the use of Address Windowing Extensions (AWE). You will often hear terms such as PAE, AWE, and even VLM (Very Large Memory) tossed about interchangeably. They essentially mean the same thing - the ability on a 32-Bit OS to address memory, indirectly, beyond 4 GB.
Oracle Implementation of AWE on Windows

Oracle implements AWE support on Windows by the addition of an init.ora parameter called USE_INDIRRECT_DATA_BUFFERS. By setting this value to true, Oracle will use the AWE APIs on Windows to allow the oracle executable to address memory beyond 4 GB – up to a maximum of 16 GB. However, UNLIKE the setting of the /3GB switch, this memory cannot be used by all Oracle components. Recall that the memory used by Oracle is comprised of the SGA, the PGA, overhead for the process, and the stack for all threads.

When setting the value of USE_INDIRRECT_DATA_BUFFERS to TRUE, Oracle will only allow you to increase the database buffer cache to make use of that additional memory, but you can increase the buffer cache to a value as high as you wish, up to the maximum of 16 GB. Note that the 16 GB maximum includes the buffer cache plus the rest of the memory used by the process, so a realistic maximum value for the buffer cache alone is more like 12 GB, provided you have that much memory in the system.

In order to address this extra memory indirectly, a window must be created within the normal 3 GB address space. This window is defined by a registry entry called AWE_WINDOW_MEMORY. This value does NOT have to be explicitly set. If it does not exist in the registry, a default value of 1 GB is assumed. If you do not want to use a window size of 1 GB, you must add this value in the key for your particular ORACLE_HOME.

For example:

HKEY_LOCAL_MACHINE\SOFTWARE\ORACLE\KEY_OraDb10g_home1

Where “KEY_OraDb10g_home1” is the key associated with your particular ORACLE_HOME, as shown in Figure 3. If USE_INDIRRECT_DATA_BUFFERS is set to the default value of FALSE, the setting for AWE_WINDOW_MEMORY is ignored.

When using indirect data buffers, you must change the formula for calculating the total amount of memory used within the 3 GB address space to ONLY include the AWE_WINDOW_MEMORY portion of the buffer cache. The remainder of the buffer cache should be excluded from calculations to determine how close you are to the 3 GB address space. So, the new formula for this would be along the lines of:

Total Memory Used within 3GB =

AWE_WINDOW_MEMORY (+)
Non-Buffer cache portion of the SGA (i.e. Shared_Pool, Large_Pool, Java_Pool, Stream_Pool and Log_Buffers) (+)
PGA (+)
Process Overhead (+)
(Thread Stack * # of threads)

Note also that the thread stack is variable, as it may change from 1 MB if the orastack utility has been used. This will not give you the total amount of memory used by the Oracle process, but it will tell you how much of that memory counts towards the address space limitation of 3 GB. This is also the same value that will be shown by the virtual bytes counter in Perfmon, as Perfmon will not show the indirectly addressed memory.

To help understand this further, consider as an example a case where you have a buffer cache alone that is 6 GB. You would only count 1 GB (assuming the value of AWE_WINDOW_MEMORY is left at the default) of that 6 GB in the above calculation.
The remainder of the buffer cache does not count against the normal 32-Bit address space limitations, because it is addressed indirectly.

When a database block buffer is needed by the database, it is mapped into the window, whose size is defined by AWE_WINDOW_MEMORY, and then can be accessed by the RDBMS. If the window fills and additional blocks need to be accessed, then the window is “redrawn” to exclude less recently used blocks and to include the newly requested blocks. There is no memory copy done – just a redrawing of the window – i.e., one buffer may be unmapped and another buffer will be mapped, meaning the window is essentially “reshaped”. The “shape” of the window may change, but the total size of the window itself will not change unless the value for AWE_WINDOW_MEMORY is changed and the database service restarted.

The process of mapping and unmapping buffers will add some overhead beyond what would normally be experienced if a block could be directly addressed within the 3 GB space. However, this mapping/unmapping of blocks in memory should be much faster than a disk I/O, which would be the alternative.

Thus, the only real disadvantage of using indirect data buffers is that you must use old-style init.ora parameters for defining the buffer cache – i.e., you must set DB_BLOCK_BUFFERS instead of DB_CACHE_SIZE. This, in turn, disables the automatic SGA tuning features introduced in Oracle10g by the SGA_TARGET parameter. Aside from this, there is some additional administrative work that must be done in calculating appropriate values for AWE_WINDOW_MEMORY. For more details on implementing Address Windowing Extensions for Oracle on Windows, please refer to Metalink Note # 225349.1.

Using RAC to Scale on Windows
Yet another way to increase the addressable memory for the database is to increase the number of processes. As noted thus far, the 3 GB address space limit applies on a per-process basis – and each Oracle instance runs as a single process. In traditional database parlance, a single instance is accessing a single database. But, if you throw Oracle RAC (Real Application Clusters) into the mix, you now have multiple instances accessing a single database. The RAC architecture puts all of your database files on a shared-everything storage system, which can be accessed simultaneously by as many as 64 different server nodes, each running its own separate oracle.exe.

In a RAC environment, the oracle executable comprising the Oracle instance would have its own separate process on each node. The process overhead of approximately 100 MB would be the same on each node, as would the SGA – but user sessions can be spread across multiple nodes, meaning that the amount of PGA memory and thread stack memory is not all concentrated within a single process, but is instead spread across many processes, running on as many separate nodes as you need. Clustering together several Windows machines running on inexpensive hardware is an effective way of scaling the database to meet the demands of organizations of every size. In a future article, I will go into more detail on implementing RAC and CRS on Windows.

Using 64-Bit Windows.
Finally, I said at the beginning of this article that a majority of customers on both Windows and Linux are still running in 32-Bit environments. However, that tide is turning and more and more customers of both operating systems are turning to 64-Bit Hardware. Up to now, the focus of our discussion has been on 32-Bit hardware, but I will turn now to the options on the 64-Bit platform, in particular regarding Oracle on Windows.

The primary advantage of 64-Bit Windows with 64-Bit Oracle running on top is that the addressable memory for a single process jumps from a maximum of 3 GB to a maximum of 8 TB (Yes – terabytes). This memory is directly addressable by the 64-Bit oracle.exe. As such, if running on a 64-Bit version of Oracle on Windows, it is no longer necessary to concern yourself with issues such as setting the /3GB switch, or using the /PAE switch or AWE_WINDOW_MEMORY, etc. The process will directly address as much memory as you can realistically...
put into the machine, with no special tweaking or switches.

The complicating factor, and the reason that this warrants more discussion, is that there are multiple flavors of 64-Bit chips. The two main flavors of chips are the Intel Itanium flavor, and the x86_64 flavor. (which includes the AMD Opteron chip, and the Intel EM64T chip). These flavors of chips differ from one another architecturally, and therefore require a separate version of the operating system and a separate version of Oracle.

The Intel Itanium chips are on their second generation, and Windows 2003 has supported Itanium chips with a 64-Bit version of Windows 2003 since it was first released. Oracle on 64-Bit Windows 2003 (Itanium) has been available from version 9.2.0.3 and onwards. However, the Itanium chips can ONLY run 64-bit Windows 2003 – they do not support installing a 32-Bit version of Windows on an Itanium chip.

The x86_64 chips have the advantage of being able to run either a 32-Bit or a 64-Bit operating system. However, Windows did not release a 64-Bit version of their OS for the x86_64 chips until the Spring of 2005. Therefore, while it was possible to have a machine with x86_64 chips, which were running a 32-Bit version of Windows 2003, it was not possible to run 64-bit apps on those chips until just recently. By the way, installing 32-Bit Windows 2003 on an AMD chip, and then running the 32-Bit version of Oracle on top of that is fully supported. But, if that were the case, there is no distinction between 32-Bit Oracle on a Pentium or equivalent processor, and Oracle on 32-Bit x86_64. The same address space limitations would still apply.

Since there was no 64-bit version of Windows for the x86_64 until just recently, Oracle10g Release 1 was not released with a version that runs on 64-Bit x86_64 Windows. Only 64-Bit versions of Oracle9i and Oracle10g Release 1 were released to support the Itanium chip. The first release of Oracle that will run on the AMD (x86_64) platform will be 10g Release 2, expected to be released in late summer of 2005. With the release of Oracle10gR2 for Windows, the 64-Bit choices will be greatly increased.

Cool

The stated goal of this article was to assist Oracle DBAs on Windows with a successful implementation of their database, whatever stage you are at in the implementation, and whatever the size of your organization. Hopefully, with the tips contained here-in, you will be able to echo my sentiments that Oracle on Windows is very cool.

Scott Jesse, Oracle Corporation
– Scott has worked for Oracle Support for the past nine years and is currently a member of the High Availability Advanced Resolution Team. He works primarily on Windows and Linux RAC environments, as well as with Oracle Fail Safe and Data Guard. Scott is the co-author of two Oracle Press titles: “Oracle9i for Windows 2000 Tips & Techniques”, published by Oracle Press in December 2001, and more recently, “Oracle Database 10g High Availability with RAC, Flashback and Dataguard”, published by Oracle Press in April of 2004. Scott may be contacted at Scott.Jesse@ERPtips.com
